Pulmonary Alveolar Microlithiasis (PAM)

Somkiat Wongtim

A case of pulmonary alveolar microlithiasis is reported. A 50 year old female experienced with symptoms of episodic cough and dyspnea on exertion for 2 years. On physical examination, she was found to have tachypnea, and widespread crepitation was heard over both lung fields. The chest radiograph was reported as fine miliary shadows, particularly in the lower lung zone. Flexible fiberoptic bronchoscopy and lung biopsy was performed. The histologic finding of the lung tissue showed laminated calcospherites in alveolar spaces which was the typical pathology for pulmonary alveolar microlithiasis. The treatment was symptomatic and finally she was lost in follow up.

Key words: Pulmonary, Alveolar, Microlithiasis, Calcification of the lung.

ให้รายงานผู้เป็นโรคหนึ่งในดูแลมดับหนึ่งราย ซึ่งเป็นผู้ป่วยหญิงอายุ 50 ปี มีอาการไอเรื้อรังเป็นระยะ และเหนื่อยง่ายนาน 2 ปี จากอาการตรวจพบว่าผู้ป่วยหายใจเร็ว และได้รับส่งผลิตภัณฑ์ในปกติที่สองช่วงที่ไม่หมด จากอาการสั่นสะเทือนกว่ามีจุดเล็กๆกระจอกเล็กในปกติ โดยเฉพาะส่วนล่างหน้าที่มีผู้ป่วยได้รับการส่งกล้องตรวจห้องตะลุม และคัดชันเนื้อปอดไตรภูมิ ผลการตรวจทางพยาธิวิทยาพบว่ามีก้อนเนื้ออยู่ในท้อง ซึ่งเป็นลักษณะเฉพาะของโรค ผู้ป่วยได้รับการรักษาตามอาการแต่ไม่ดีขึ้น และขาดการติดต่อไปยังสุด
Pulmonary Alveolar Microlithiasis (PAM) is a rare condition of unknown etiology. The first case of PAM was reported by Harbitz in 1918. He described the round or oval lamellated concretions as lying in the intraalveolar tissue of the lung.\(^1\) Many cases of this rare disease have now been reported ranging from that in a premature infant to that in an old man, with the majority of cases being found in patients during the fourth to sixth decades of life.\(^2-3\) Chinachoti N. and Tangchai P. reported the first case of PAM in Thailand in 1957.\(^4\) Since then there have been a few reports of PAM in Thai patients.\(^5-6\) The following is a report of a case of PAM at Chulalongkorn Hospital.

**Case report**

A 50-year-old female patient, experienced for two years episodic cough with slightly mucoid sputum and dyspnea on exertion. She had been working in a starch factory in Cholburi for more than 10 years. Physical examination revealed that she had mild tachypnea, respiratory rate 24/min, pulse rate 90/min, blood pressure 120/80 mmHg, and no fever. There were widespread crepitations throughout the lung field, but no evidence of cardiac failure.

Laboratory findings were: hemoglobin 13 gm%, white blood cells 7000/cumm, with PMN 75% and normal platelets. Blood chemistry was normal. Sputum Gram stain and AFB stain revealed no significant organism. A chest radiograph showed fine miliary shadows, particularly in the lower lung zone with some areas of fibrosis (Fig.1).

Spirometry showed that FVC was 1500 ml (48% of predicted value). FEV1 1380 ml (92% of FVC). Arterial blood gas values were pH 7.46, pCO2 32 mmHg and pO2 62 mmHg.

Flexible fiberoptic bronchoscopy and lung biopsy was performed. The bronchial mucosa was slightly pale. Histologic findings of the lung biopsy showed laminated calciphospherites within alveolar spaces and slight fibrosis of the alveolar wall (Fig. 2). PAM was diagnosed. She was treated with corticosteroid; there was little subjectively observed improvement. One year later, she developed cor pulmonale and thereafter was lost to follow up.

**Figure 1.** Chest radiograph showing dense miliary shadows, particularly in the lower lung zone with some area of fibrosis.

**Figure 2.** Lung biopsy showing laminated calciphospherites within alveolar spaces and slight fibrosis of alveolar wall.

**Discussion**

The differential diagnosis of diffuse reticulonodular infiltrations in the lungs includes the presence of:
1. infectious diseases such as miliary tuberculosis, histoplasmosis;
2. malignancy such as metastatic carcinoma, alveolar cell carcinoma;
3. environmental lung diseases such as pneumoconiosis;
4. collagen vascular diseases; and
5. rare diseases such as idiopathic pulmonary fibrosis, hemosiderosis, pulmonary alveolar proteinosis, pulmonary alveolar microlithiasis, etc.

Definite diagnosis is usually made from a lung tissue biopsy taken either by transbronchoscopy or open thoracotomy.

This patient experienced a history of chronic cough and progressive dyspnea for two years; she had been a worker in a starch factory for a total of 10 years. She was investigated by fiberoptic bronchoscopic lung biopsy. Lung tissue biopsy showed intraalveolar calcospherites and slight fibrosis of the alveolar wall which is characteristic of pulmonary alveolar microlithiasis (PAM). PAM is a rare disorder characterized by intraalveolar calcific concretions distributed evenly throughout both lungs. There is no definite sex predominance. In early courses of the disease, sputum is usually mild when compare with abnormalities seen in chest radiography. The common manifestations are nonproductive cough and breathlessness on exertion while physical examination usually is normal. Over many years of duration of the disease, the symptoms become worse, with progressive dyspnea, cyanosis, polycythemia, hemoptysis, respiratory failure and cor pulmonale.\(^{(5)}\)

In early cases, respiratory function tests are normal. As the disease progresses, the typical features of a 'restrictive defect' are found with diminished total lung capacity (TLC) and vital capacity (VC), without evidence of airflow obstruction. In this patient, the spirometry showed that FVC was 48% of predicted value. Arterial blood gases showed mild to moderate hypoxemia. Resting \(\text{PaO}_2\) may often have been normal, but an increased (A-a) \(\text{PO}_2\) difference and diminished diffusing capacity were usually found.

The findings on the chest radiograph were fine, dense mottling density throughout both lung fields, predominantly at the bases. Histologically, numerous laminated calcospherites were found within the alveolar spaces. These varied in size from 0.02 to 3 mm, and stained blue with hematoxylin and eosin. Alveolar walls were usually normal, but late in the course of the disease cellular infiltration and fibrosis might occur.

The etiology of PAM is un clear. In has been hypothesized that PAM results from precipitation of calcium at the alveolar interface. Calcification within alveolar septa in a case of PAM associated with 'milk alkali syndrome' has been reported to be an etiologic feature of PAM.\(^{(6)}\) In this case, it may have resulted from breathing in the starch powder at the factory where the patient worked. It has been suggested that PAM is genetically determined and is due to an inborn metabolic error because there is strong evidence of familial history. There is no effective treatment for pulmonary alveolar microthiasis. Although many therapeutic measures have been suggested, such as corticosteroid, chelating agents, broncho-alveolar lavage, none is effective. However, supportive care may relieve symptoms.\(^{(7)}\)

In conclusion, PAM is a rare disease and it is usually neglected in the differential diagnosis of diffuse reticulonodular infiltrations in the lungs. The etiology is unknown, however, it may be resulted from the precipitation of calcium at the alveolar interface. There is no effective treatment for this disease. Whole lung bronchoalveolar lavage may be effective for the treatment of pulmonary alveolar microlithiasis.
